1.0 INTRODUCTION

The trigger front-end device for the DTBX chamber[1] of the CMS muon detector is the "Bunch crossing and Track Identifier"[2]. The best efficiency to noise ratio in the operating background conditions is achievable only with a careful chip setup: the BTI has many programmable parameters like angular acceptance, time filters, drift velocity and wire dead time. The BTI can be programmed either via JTAG chain or via a parallel interface using the trigger data port for back-propagating trigger parameters from the Trigger Server up to the BTIs through the TRACOs[3].

System testability are good owing to built-in self test logic and JTAG implementation.

2.0 SPECIFICATIONS

The BTI detects, with constant latency, tracks crossing the Superlayer, consisting of four layers of staggered drift tubes, and measures the impact parameters. The BTI, by means of a generalized mean-timer method, is able to identify tracks leaving a signal in a minimum of three out of four tube planes, making its operation tolerant to tube inefficiencies and δ-rays. Each wire signal is internally stretched in order to assure that only a single hit is considered in the track fitting algorithm and when more than one track is recognized in the same bunch crossing cycle, only one is sent to the next trigger preferring clean tracks (four out of four hits).

The CMS trigger requires a position resolution in the millimeter range and the best possible angular resolution to reach a good p_T sensitivity for a cut at high momentum[4] and to reduce the probability of a "ghost track" reconstruction. The angular acceptance of BTIs looking for tracks in the R-φ plane should be at least ±20° with respect to the normal to the chamber

[3] M. De Giorgi et al, "Design and Simulations of the Trigger Electronics for the CMS Muon Barrel Chambers", First Workshop on Electronics for LHC experiments, CERN/LHCC/95-96,October 1, 1995 pg. 222-227.

[4] A. Kluge et al, "Track Finding Processor in the CMS Muon Trigger", First Workshop on Electronics for LHC experiments, CERN/LHCC/95-96,October 1, 1995

because 20° is the incidence angle of high p_T muons[5] with chamber edges. BTI capability to trigger on low p_T muons depends on its angular acceptance

The chamber trigger electronics is designed for high reliability: mulfunctioning devices can be easily identified, running built in self tests, and then isolated with only minor and local efficiency losses owing to system redundancy.

3.0 SCHEMATICS

The BTI looks at 9 wires of a Superlayer numbered as shown in Fig.3.0.1.

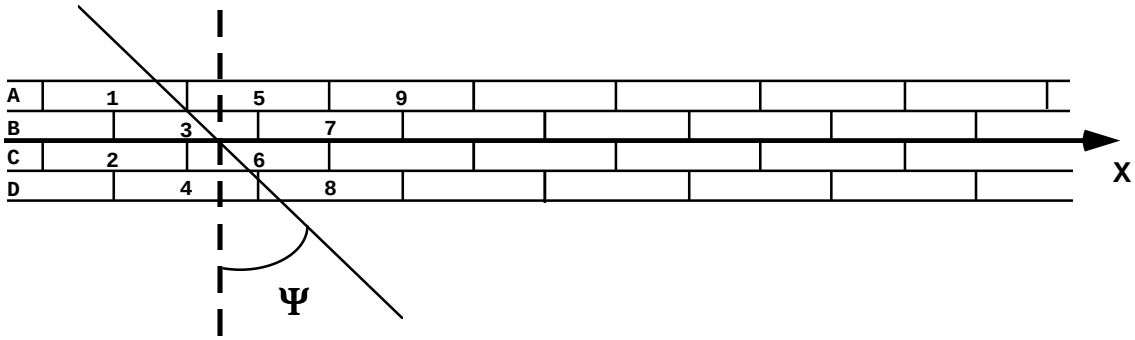

Fig. 3.0.1:Chamber section in the bending plane and BTI allocation.

The geometrical angular acceptance of a BTI is ±57deg (wrt normal) for a wire matrix with a section of 40x13 mm^2; more generally the acceptance is:

$$\Psi_{geo}^{\max} = arc\tan\frac{L_d}{h} \qquad \text{Eq.1}$$

where L_d is half the wire spacing in a tube plane and h is the distance between two adjacent wire planes. The device however is fully efficient only up to

$$\Psi_{eff}^{\max} = arc\tan\frac{2L_d}{3h} \qquad \text{Eq.2}$$

Track whose angles are higher than Eq.1 are not fully contained in a single BTI; and track angles higher than Eq.2 lead to a poor bunch crossing identification efficiency.

[5] CMS Technical Design Report, CERN/LHCC 97-32, (1997).

The BTI capability to identify the bunch crossing relies on a linear relation between hit drift time and distance from the wire, characteristic of the drift cell. The DTBX drift cell, well studied and tested[6] has good linearity up to 30deg tracks, where the linearity error is still less than half a bunch crossing cycle. However its linearity worsen very fast increasing the angle making the effective acceptance of the BTI (Ψ^{MAX}_{eff}) a reasonable limit. The BTI chip block scheme is shown in Fig.3.0.2.

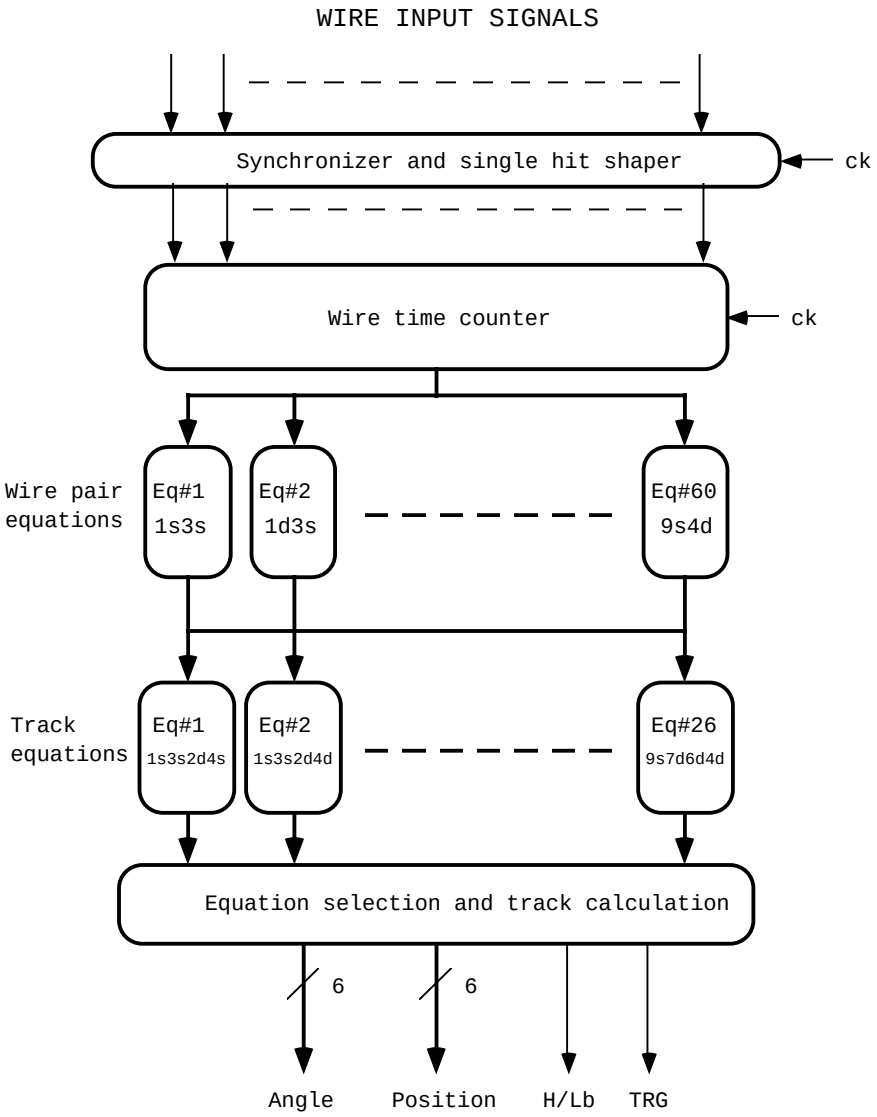

Fig. 3.0.2: BTI block scheme.

3.1 Sync and Shaper

The "Sync & Shaper" block is the interface to the 9 discriminated wire signals coming from the analog front-ends. The inputs w<9:1> are TTL level compatible rising edge triggered with a minimum pulse width of 3ns (see Appendix A for BTI technical specifications). The circuit latches the inputs and stretches them up to a programmable time according to the

[6] I. Lippi et al, "Performance of the Drift Tubes for the Barrel Muon Chambers of the CMS Detector at LHC", Nuclear Physics B (proc. Suppl.) 54B (1997) 237-244.

parameter DEAD; the input shaper is not retriggerable in order to reject high frequency double pulses. Of course DEAD must be set according to the drift velocity to minimize tube dead time (see Appendix D for drift velocity and correspondent dead time settings).

3.2 Angle and Position Equation Counters

The equation counters are simple processors working on every possible tube couple (see equation list in Appendix B) and generate the angle (wrt normal) or the position (along the plane in the middle of the Superlayer) of the crossing track using an extension of the mean-timer method[7]. The output of these processors, being generally different at each clock cycle, is correct only a fixed time after the track origin, depending on the drift velocity.

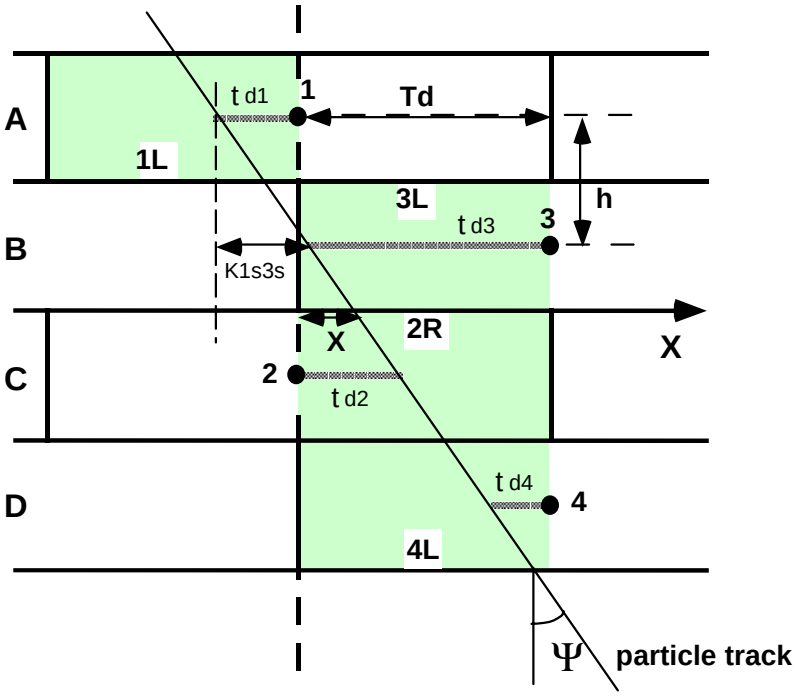

Fig. 3.2.1: 1L3L2R4L track pattern example. Are into evidence the geometrical meaning of the angular parameter k1s3s given by the equation counter looking for tracks crossing the left sides of tubes 1 and 3; and the value x of the track position along the BTI middle plane.

The angle equations give an integer parameter *k*:

$$k = k_g \bullet \tan\Psi + k_0 \qquad \text{Eq.3}$$

where k_g and k_0 depend on drift velocity:

[7] F.Gasparini et al, "Performance of a DTBX prototype", Nuclear Instruments and Methods in Physics Research A 344(1994) 137-142

F. Gasparini et al, "Further studies on a DTBX prototype for the CMS muon detector at LHC", ", Nuclear Instruments and Methods in Physics Research A 360(1995) 507-511.

$$k_g = \frac{H}{v_d \bullet t_{ck}}$$

$$k_0 = \frac{L_d}{v_d \bullet t_{ck}}$$

where v_d is the drift velocity and t_{ck} is equal to 12.5ns. Ψ is the track angle referred to the normal to the chamber. The geometrical meaning of the parameter k is shown in Figure 3.2.1.

The worst sampling resolution is for orthogonal tracks:

$$\Psi_{err}^{\max} = \arctan\left(\frac{v_d \bullet t_{ck}}{H}\right)$$

If D is the track intercept distance, along the plane in the middle of the Superlayer, from the axis of wires 1 and 2, the position equations give an integer parameter x that is the track intercept:

$$x = \frac{D}{2v_d \bullet t_{ck}} \qquad \text{Eq.4}$$

Given a track pattern all the 6 involved wire couples can give a (k,x) parameter estimation. The 6 k-equations are used to identify the track bunch crossing looking for a coincidence of values, the x-equations are considered only when the alignment of the k-equations is found; therefore only a subset of 2 x-equations per pattern was implemented. If a wire signal is spoiled by a δ-ray or is missing, only 3 out of 6 k-equations will align at the right time giving a low quality trigger. The x-equations (from BC and AD wire couples) will be used depending on the k-equation alignment found, as given in Table 3.2.1.

Track types	**X-equation**
Clean track	eqAD
A missing	eqBC
B “	eqAD
C “	eqAD
D “	eqBC

Tab 3.2.1: x-equation selection for all possible track types.

In Fig. 3.2.1 a track crossing wires 1, 2, 3 and 4 with an angle Ψ and a position x is shown. The estimation of k given by the wire couple 2-3 is

$$Eq_{23}(t) = 2t - (T + ts_3 + ts_2)$$

if the time after the wire signals detection for wires 2 and 3 are t_{s2} and t_{s3} and T is the maximum drift time:

$$ts_i = t - td_i$$

Equation $Eq_{23}(t)$, evaluated at the right time t=T gives

$$Eq_{23}(T) = td_3 + td_2 - T = k23$$

The same technique applied to all the wire couples, gives the 6 k-equations. It can be shown that while the k-equation of a wire couple crossed by the track between the wires is time dependent (increasing or decreasing its value with time) those of wire couples crossed from the same side are time independent giving immediately the k parameter of the track. This is the reason why the BTI track fitting algorithm has a limitation in the angular acceptance: when all tracks pass to the right or to the left of the wires the BTI is not able to identify anymore the parent bunch crossing. This happens also for some trigger pattern where one tube plane is not considered; these patterns are called x-patterns and are disabled unless the flag XON is set high.

Similar equations can be written for the *x* parameter. Appendix B gives the description of all the k-equations and the x-equations.

3.3 Pattern Recognition

Track pattern validation (see the pattern list in Appendix C) and the identification of the parent bunch crossing are performed by this block. Every pattern block looks for a matching of the angles given by 6 equation counters called eqAB, eqBC, eqCD, eqAC, eqBD and eqAD where the letters A,B,C and D can be replaced by the wire number of the relative plane in the Superlayer.

Each equation is matched to eqAD, since this one is giving the best determination of the k-parameter. The matching tolerance of eqAB, eqBC and eqCD has a programmable acceptance (see the use of ACx parameters in paragraph 4.0: Internal Register Files) while the matching tolerance of eqAC and eqBD is fixed to ±1. When all the 5 equation values match with eqAD within the given acceptance a high quality trigger (HTRG) is generated with angle and position values. It might happen that only three wire planes give a clean signal, due to a missing or spoiled wire signal. If wire plane A cannot be considered, eqAB, eqAC and eqAD are no more valid; the matching can be found only between eqBC, eqCD and eqBD where the last one is giving the best k-parameter estimation. Table 3.3.1 showes the k-equation matching scheme implemented for all the possible track types.

Track types	eqAB	eqBC	eqCD	eqAC	eqBD	eqAD
Clean track	x	x	x	x	x	Ref
A missing		x	x		Ref	
B "			x	x		Ref
C "	x				x	Ref
D "	x	x		Ref		

Tab 3.3.1: k-equation matching scheme for all possible track types.

Every time only 3 out of 6 equations match, a low quality trigger (LTRG) is given. The use of a quality bit (H/L pin) allows the next device in the trigger chain to distinguish between clean tracks and potentially wrong triggers. Low quality triggers are mainly due to the so called “ghost tracks”: out of time alignments of virtual tracks due to the left/right ambiguity of the drift cell.

3.4 Pattern Selection

If several track patterns give a trigger at the same time, only one is selected preferring a high quality track. If the pattern quality is the same a default encoded order is used.

3.5 LTS Filter and Angle Window Comparator

The capability to trigger on "dirty" tracks (three out of four aligned hits) causes the BTI to trigger frequently at the wrong time, either before or after the right trigger time, even processing a clean track. The phenomenon, called "ghost track" generation, is the main source of trigger noise.

The “ghosts”production is a purely geometrical mechanism, due to the left-right ambiguity (see Fig. 3.5.1): when a track signal is detected at the BTI input, the drift direction is unknown. In order to be efficient, and to be able to trigger even if only three out of four hits are good, all the combinations and possibilities must be evaluated, at the same time, making the right trigger output of a clean track to be associated with a mean value of 3 low quality triggers associated to “ghost tracks”. These wrong triggers are distributed in time around the right one in the range of ±8bx. In the example shown in Fig. 3.5.1 a clean stright track has two associated ghosts. The first (ghost #1) is generated assuming that the signal coming from wire 2 has been spoiled by a δ-ray. The second one (ghost #2) is generated considering that the signal from wire 5 could be missing because of a local inefficiency.

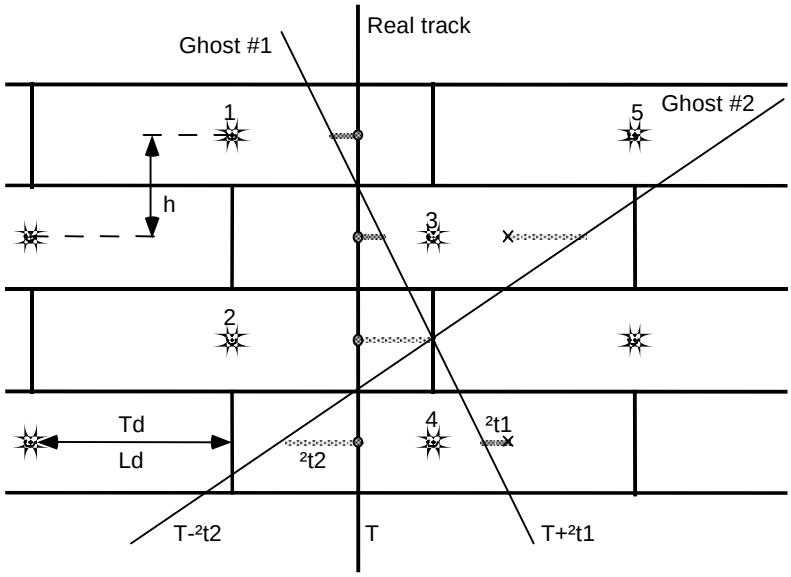

Fig. 3.5.1: “Ghost tracks” generation example.

In order to reduce the number of "ghost" triggers, the cancelation of low quality triggers in the range (-1bx,+8bx) about a high quality trigger is very efficient and latency inexpensive; this Low Trigger Suppression filter is programmable (LTS and SET registers).

As described elsewhere[3] each BTI of the chamber outer Superlayer is interfaced to three Track Correlators (TRACO). In order to reduce the probability to generate multiple triggers from single tracks, an angular

filter has been included in order to send to each TRACO only those tracks that could be fully contained in it. The trigger strobe is splitted into three signals, one for each TRACO, activated only if the track angle is within the respective programmable window. Quality bit and angle/position lines are common to the three TRACOs. The BTI trigger output bus consists of the three trigger strobes TRGL, TRGC, TRGR, the quality bit H/L and the data bus AP<5:0> where angle and position are multiplexed at 80MHz.

3.6 Control Logic

This block contains a JTAG[8] interface and a bidirectional parallel interface. The JTAG port (tms,tck,tdi,tdo) can be used either to control chip interconnections and to program internal registers. An additional capability of this interface is the monitoring of chip activity without interfering with the trigger function. This can be performed simply reading the snap registers connected to the input signals and to the output bus (see snap registers description in the next section).

The parallel interface, much faster than the JTAG port, can program all the BTI internal registers and is used only as a backup solution for BTI access. Using the angle/position trigger bus as data bus the TRACO has the possibility to access the internal registers of the connected BTIs and downstream the Track Server Sorter (TSS) can access all chamber TRACOs. Associating a specific address to the BTI input port (WIN) data can be exchanged with the front-end electronics as described in 6.0: Parallel Interface.

3.7 Reset Logic

At power on all trigger chips can be put in a default state using the asynchronous reset line HRSTB. The synchronous reset (SYRSB) can be used to clear all internal registers with the exception of the configuration parameter register file.

An additional synchronous reset command (SNRSB) clears only the snap registers.

4.0 INTERNAL REGISTER FILES

BTI registers are grouped into 4 files of 6 bit words accessible using dedicated JTAG instruction addresses: configuration, test, snap and boundary.

4.1 Configuration

This register file collects all the set up registers for the BTI trigger operation and has to be programmed after a power-on reset (HRSTB low):

- ST43 and RE43 are programmed to set the drift velocity from 44.4 to 66.7 μm/ns as described in Appendix D.
- WEN is the input wire mask register (one bit per wire): when a bit is set low it disables the corresponding wire input.
- DEAD is the wire dead time that should be set as suggested in Appendix D in order to maximize the efficiency/noise ratio.

[8] IEEE Std 1149.1-1990 "IEEE Standard Access Port and Boundary-Scan Architecture", May 21, 1990

- LH, LL are the angular window limits for the left TRACO (interested to negative track angles): a "left trigger" output (LTRG) is generated when:

LL <= track angle <= LH

CH, CL and RH, RL are the angular limits respectively for the centered TRACO and for the TRACO to the right.

- TSTON, TEST and TEN are flags used for BTI self test purposes as described in 8.0: Test and Debug Features.

Add	b5 (MSB)	b4	b3	b2	b1	b0 (LSB)

13	ach<1>	ach<0>	-	-	-	-

Tab 4.1.1: Configuration register file.

- XON is a flag activating the so called X-patterns: the low quality track patterns associated to tracks passing on the same side of the three wires. Setting XON high enables the X-patterns and rises the efficiency but more out of time triggers are generated, being the time resolution of "X-patterns" intrinsically poor and dependent on track position.

- RON flag enables the redundant patterns, that are those patterns already covered by the neighbouring BTIs. Setting RON high the BTI extends its acceptance range to recover part of a neighbouring BTI inefficiency, or to optimize the Superlayer geometric acceptance (if the BTI is the last one).

- AC1, AC2, ACH and ACL allow to program part of the alignment acceptance of equation counters in the track pattern blocks. The track patterns look for an equation counter matching (see Appendix C) with default tolerances set depending on equation and on pattern. Some pattern is critical from the noise point of view or too much sensitive to drift cell nonlinearity as in the case of patterns triggering only on large angle tracks. For this reason the default maximum alignment error of 2 between eqAB, eqBC and eqCD whit respect to eqAD can be overwritten using the ACx parameters as described in Table 4.1.2.

ACx	Matching of eqX and eqAD
00	eqX-1 <= eqAD <= eqX+1
01	eqX <= eqAD <= eqX+2
10	eqX-2 <= eqAD <= eqX
11	eqX-2 <= eqAD <= eqX+2

Tab 4.1.2: Equation alignment programmable tolerance.

The section 7.0: Operating Instructions gives more information about the use of these parameters.

4.2 Test

This register file (Tab. 4.2.1) is mainly used to run self tests of the BTI but can be used also to mask specific track patterns:

- PTMS is the track pattern mask. A pattern is disabled if the correspondent bit is set low.
- TCEN is the equation counter group test enable and is used only for chip validation as described in section 8.0: Test and Debug Features.
- WD1 ÷ WD9 are the drift time registers used to emulate a track. WD1 is the drift time in 12.5ns units for the signal of wire 1; when set to zero it gives no signal. The section 8.0: Test and Debug Features gives more information about track emulation procedure.

Tab 4.2.1: Test register file.

4.3 Snap

This register file (Tab. 4.3.1) is used for chip monitoring purposes:

- SNW is the snap register of the input wires: a bit is set high when the correspondent wire is hit by a track.
- LPOS and LANG are position and angle of the first low quality trigger given from the BTI after the last reset.

- In LQTR are stored LTRG (bit 2), CTRG (bit 1) and RTRG (bit 0) of the first low quality trigger given from the BTI after reset time.
- HPOS and HANG are position and angle of the first high quality trigger given from the BTI after reset time.
- In HQTR are stored LTRG (bit 2), CTRG (bit 1) and RTRG (bit 0) of the first high quality trigger given from the BTI after reset time.

- RE23, ST2, ST ÷ ST7 are the internallly calculated drift velocity parameters as given in Appendix D. In particular ST is the maximum drift

time expressed as number of CK cycles (12.5ns), normally ranging from 26 to 36.

The snap registers are cleared by a SNPRST signal and are written only once, after the first trigger occurrence.

4.4 Boundary Scan

This register file (see Tab. 4.4.1) is accessible by JTAG and is used only for Trigger board connectivity tests.

5.0 JTAG INTERFACE

The JTAG[7] port is available for interconnection testing and for BTI registers programming. The implemented instructions are the mandatory Extest, Bypass and Sample, and the dedicated Config, Test and Snap as described in Tab. 5.0.1.

The first one (Extest) is used for PCB testing and in general for system interconnect verification. This function allows to write in all chip outputs a value and to verify that the same pattern can be received at the inputs of downstream connected devices.

The bypass instruction is used to skip a device in the JTAG chain.

Sample instruction allows to read BTI periphery without interfering with chip operation.

Dedicated instructions are used to access Configuration, Test and Snap register files.

Tab 5.0.1: JTAG instruction set.

6.0 PARALLEL INTERFACE

The BTI registers can be programmed very efficiently through a parallel interface. This port is controlled by three input lines: PRGB, STRB and R/W. The I/O data bus uses the same set of pins as the angle/position 6 bit trigger bus. As shown in Fig.6.0.1 a low level on PRGB turns on the interface and prevents any trigger data to be generated. The internal registers can be accessed randomly or sequentially.

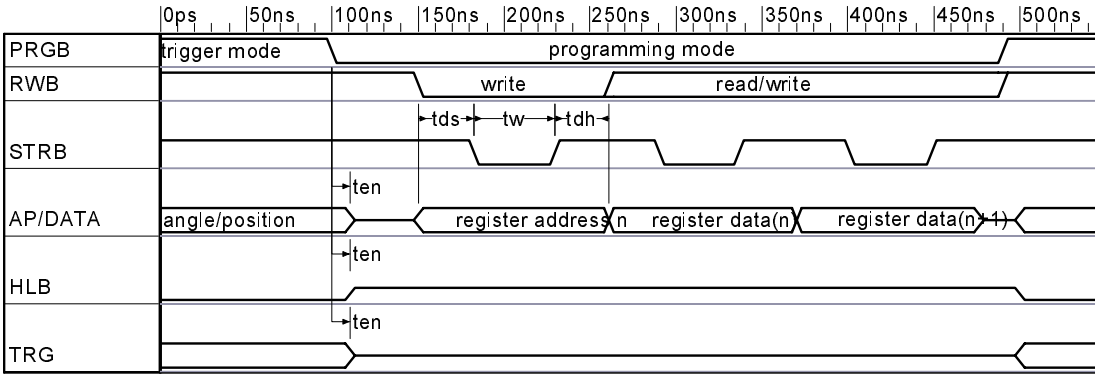

Fig. 6.0.1: Parallel Interface access timing.

After PRGB is pulled low the first input word is the address pointer and the second one is to read or write operation into the data register. If PRGB is kept low the address pointer is self-incremented and another data can be read or written into the next register. When PRGB goes high the address pointer is cleared.

6.1 Front-end interface

The backpropagation of the programming data using the parallel interface can go up to the front-end logic passing through the BTI's Front-end Interface.

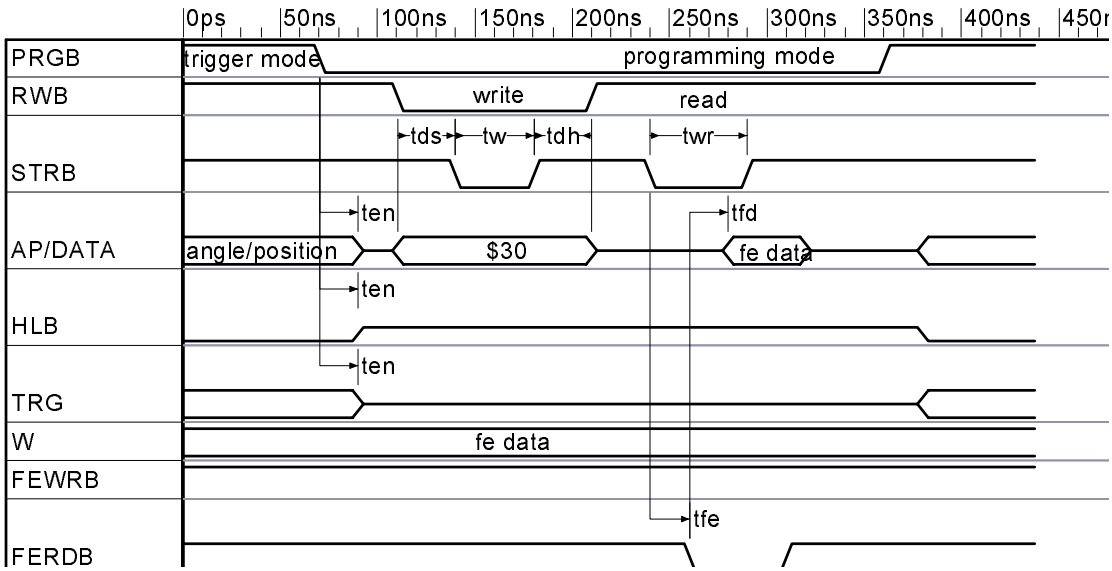

Fig. 6.1.1: Front-end Parallel Interface read operation.

The communication protocol, as shown in Fig.6.1.1 and 6.1.2 is simple: when the BTI is addressed (PRGB low) it is possible to connect the wire input port (WIN bus) to the angle/position port (AP bus) in both directions; the address of the “wire port” is 48 and can be read or written in the same way the other registers are. A read or write operation performed at this address generates a FERDB (front-end read strobe) or FEWRB (front-end write strobe) strobe signal.

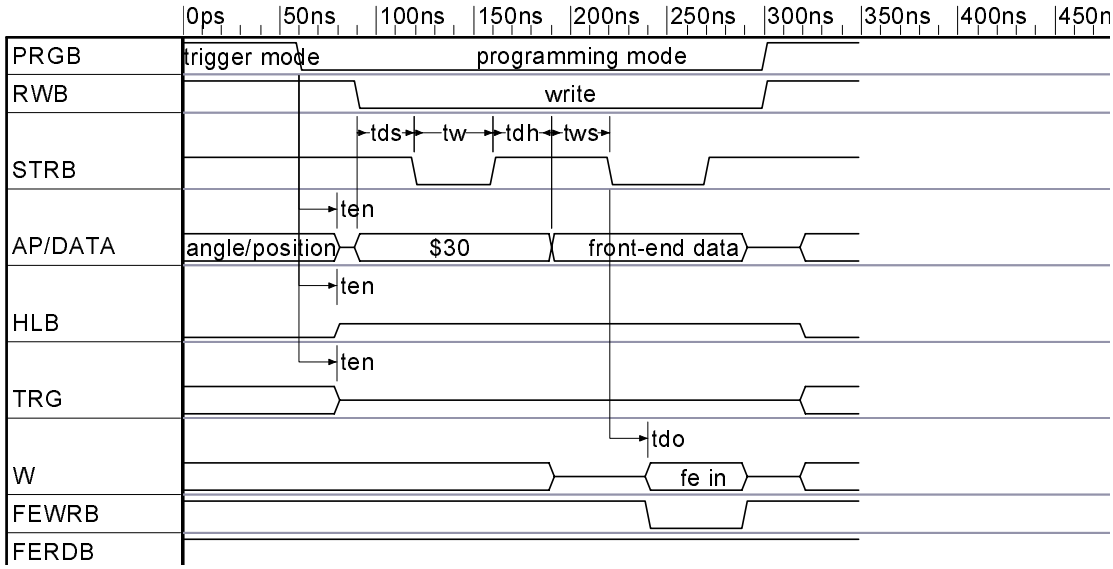

Fig. 6.1.2: Front-end Parallel Interface write operation.

7.0 OPERATING INSTRUCTIONS

BTI operations start at power on with a hardware reset command, executed pulling low HRSTB. While CK and PHI are running, the synchronous reset command SYRSB can be used to clear the internal registers with the exception of the configuration register file. A dedicated synchronous reset (SNRSB) is available to clear only the snap register file and this operation does not interfere with the triggering function.

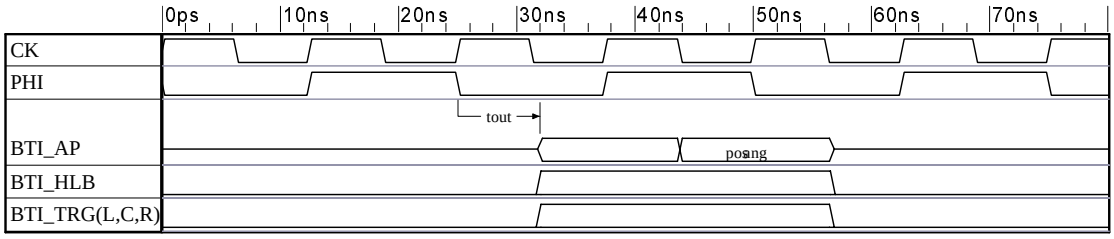

Fig. 7.0.1: BTI output timing.

CK and PHI are respectively the sampling clock and the output clock. The latched input signals coming from WIN are sampled at the rising edge of CK while trigger angle data is output at the falling edge of PHI (see the timing diagram of Fig.7.0.1). The angle value is given first (during the low phase of PHI) and then the position is output during the high phase of PHI. It is foreseen that angle/position values are sampled by TRACOs on the rising/falling edge of PHI respectively, while trigger strobes and quality bit are sampled on the rising edge of PHI. In order to enable the trigger data bus, PRGB must be high.

The BTI output is meaningless for the first 20 PHI cycles after an hardware reset (HWRST low).

The BTI trigger setup is described in the next four steps.

7.1 DRIFT CELL PARAMETERS

The cell drift velocity is the fundamental parameter of the BTI. This parameter is coded, in order to simplify internal calculations, as described in Appendix D. Once the drift velocity is measured the internal registers ST43, RE43 and DEAD must be programmed accordingly.

7.2 TRIGGER FILTERING PARAMETERS

Each input wire has a mask bit in the WEN register: noisy channels can be individually disabled by setting high the correspondent mask bit.

The trigger output can be filtered both in time and angle. LH and LL are the high and low angle thresholds for the Left Trigger (LTRG) strobe: a trigger is given by this line only if the track angle satisfies the relation LL <= track angle <= LH. The registers CH, CL and RH, RL have the same mening respectively for Central Trigger (CTRG) and Right Trigger (RTRG).

The LTS algorithm is turned on when LTS is not zero according to the following table:

LTS<1:0>	Low quality Trigger Suppression
00	none
01	after a high quality trigger for SET<2:0> PHI cycles
10	before a high quality trigger for 1 PHI cycle
11	after and before a high quality trigger (01 and 10)

Tab. 7.2.1: LTS algorithm setup.

Flags XON and RON play an important role in the trigger efficiency to noise ratio. The first one, when set high, turns on all low quality triggers of tracks passing from the same side of the wires; this enhances slightly the trigger efficiency at high angle but increases the trigger noise. RON, when set high, turns on the redundant track patterns, that is the patterns that should be covered by the neighboring BTIs. This can be helpful if the BTI

is the last one of the Superlayer or the neighboring BTI is disabled, or mulfunctioning.

7.3 TIME RESOLUTION AND DRIFT CELL LINEARIZATION

	Normal patterns tolerance wrt EqAD					**Critical patterns tolerance wrt EqAD**				
Eq.	**-2**	**-1**	**0**	**1**	**2**	**-2**	**-1**	**0**	**1**	**2**
AB	x	x	x	x	x		x	x	x	
BC	x	x	x	x	x		x	x	x	
CD	x	x	x	x	x		x	x	x	
AC		x	x	x			x	x	x	
BD		x	x	x			x	x	x	

Tab. 7.3.1: Equation alignment acceptance mask for Normal and Critical patterns: the equation counters are aligned if the difference with respect to the EqAD is within the specified limits.

	1L1 patterns					**1H1 patterns**				
Eq.	**-2**	**-1**	**0**	**1**	**2**	**-2**	**-1**	**0**	**1**	**2**
AB		x	x	x			x	x	x	
BC	x	x	x					x	x	x
CD		x	x	x			x	x	x	
AC		x	x	x			x	x	x	
BD		x	x	x			x	x	x	
	L11 patterns					**H11 patterns**				
Eq.	**-2**	**-1**	**0**	**1**	**2**	**-2**	**-1**	**0**	**1**	**2**
AB	x	x	x					x	x	x
BC		x	x	x			x	x	x	
CD		x	x	x			x	x	x	
AC		x	x	x			x	x	x	
BD		x	x	x			x	x	x	
	11L patterns					**11H patterns**				
Eq.	**-2**	**-1**	**0**	**1**	**2**	**-2**	**-1**	**0**	**1**	**2**
AB		x	x	x			x	x	x	
BC		x	x	x			x	x	x	
CD	x	x	x					x	x	x
AC		x	x	x			x	x	x	
BD		x	x	x			x	x	x	

Tab. 7.3.2: Critical track patterns acceptance mask.

Time resolution is not the same for all track patterns, being some of them more sensitive to track timing. In order to minimize the trigger noise, these critical patterns are programmed with half the normal alignment acceptance, as shown in Table 7.3.1. While for normal patterns a high quality trigger is recognised if equation counters AB, BC and CD differs from AD within +-2 and AC, BD differs from AD within +-1; for critical

patterns the AB, BC and CD equation counters have half the normal error tolerance: +-1 referred to EqAD. Unfortunately these critical patterns are mainly looking for high angle tracks where the relation between distance from the wire and drift time of a cell is not any more linear.

An effective way to reduce the drift time distortion at high angle has been found applying an offset to the alignment of eqAB, eqBC and eqCD with respect to eqAD as shown in table 7.3.2. Appendix C gives the list of patterns and the respective pattern type.

ACx	-2	-1	0	1	2
00		x	x	x	
01			x	x	x
10	x	x	x		
11	x	x	x	x	x

Tab. 7.3.3: ACx parameter coding for equation alignment acceptance.

The alignment acceptance for equation counters AB, BC and CD can be programmed setting AC1, AC2, ACH and ACL. Each track pattern type (normal, 1L1, etc.) refers to a specific combination of ACx for the acceptance of equations AB, BC, CD; the corresponding acceptances are given in Tab. 7.3.3. Standard programming values for ACx are given in Tab. 7.3.4.

AC1	00
AC2	11
ACH	01
ACL	10

Tab. 7.3.4: Default track pattern acceptance parameters.

The default settings can be changed; for example when all the ACx parameters are equal to 11 the alignment acceptance is the maximum possible (±2) giving the highest probability to trigger on distorted tracks.

8.0 TEST AND DEBUG FEATURES

The BTI chip has a built in self test logic aiming to minimize the vectors for chip validation. The validation mode is activated by flags VAL and TSTON, as explained in detail in Appendix E.

Snap registers, connected to input wire signals and output trigger data are provided for online trigger system debugging. The input wire snap flip-flops are set if a signal has been received by the BTI after the last reset (SNRSB). The output trigger data snap registers keep the full trigger information: LTRG, CTRG, RTRG, H/L, ANG<5:0> and POS<5:0> either for the first low quality trigger occurred or the first high quality trigger generated after the last reset. After a SNRSB reset command, the JTAG interface can be used to shift out the snap register data allowing to monitor the trigger activity without any interference.

Another testing facility is the possibility to disconnect by software the BTI from the chamber and to use internal programmable delays as drift cell emulators. Setting high the TEN flag makes the wire inputs WIN to be inactive. The internal registers WD1<5:0> to WD9<5:0> are the starting values of drift time counters. Once these registers are programmed to be equal to the drift times (in 12.5ns steps) associated to a test track, setting high the TSTON flag makes the drift counters to start counting down, which simulates the track signal generation. If WDn<5:0> is set to zero the relative wire doesn't give any signal. This capability to simulate real tracks can be used on the field to test the trigger chain in special situations.

APPENDIX A: TECHNICAL SPECIFICATIONS

A1: Features

. Operating voltage 3.3V ± 0.3V
. TTL/CMOS compatible inputs
. Operating speed 40MHz (80MHz WIN sampling)
. Low power 0.5µm CMOS process
. JTAG interface
. Parallel interface
. Emulation and monitoring features
. High drive capability: 6.5ns @ 150pF
. TQFP 64 pin production package
. PLCC 64 pin prototype packaging

A2: BTI PLCC64 pinout

APPENDIX B: ANGLE AND POSITION EQUATIONS

B1: Angle equations

These equations give the track slope k that is function of the track angle with respect to the normal direction according to Eq.3. The quantities sum(i,j) and dif(i,j) are the sum and the difference respectively of shift times of wires i and j. The equations, giving integer unsigned values have an offset equal to the programmed ST value.

Tab. C.1: The BTI recognizable track patterns.

Recognizable tracks are classified into patterns. Patterns are partially or totally masked in order to minimize redundancies between adjacent BTIs. cAB, cBC and cCD are the alignment acceptances respectively for EqAB, EqBC and EqCD with respect to EqAD. The four possible acceptances are specified by the programmable parameters AC1, AC2, ACH and ACL as specified in section 7.3.

xA, xB, xC and xD are the low quality trigger mask respectively for a wrong or missing A plane, B, C and D. The low quality triggers are normally enabled with two exceptions: X-type patterns (marked with X) and redundant patterns (marked with R). These two classes of low quality triggers are enabled setting high the correspondent flag XON and RON. High quality redundant patterns are enabled setting high RON.

APPENDIX D: DRIFT VELOCITY CODING

4ST3	4RE3	Vd (μm/ns)	DEAD	Latency (ns)	ST
32	**0**	**66.7**	23	400	24
32	**2**	**65.3**			24.5
33	**1**	**64**	24	425	25
34	**0**	**62.7**			25.5
34	**2**	**61.5**	25	425	26
35	**1**	**60.4**			26.5
36	**0**	**59.3**	26	450	27
36	**2**	**58.2**			27.5
37	**1**	**57.1**	27	450	28
38	**0**	**56.1**			28.5
38	**2**	**55.2**	28	475	29
39	**1**	**54.2**			29.5
40	**0**	**53.3**	29	475	30
40	**2**	**52.5**			30.5
41	**1**	**51.6**	30	500	31

42	**2**	**50**	31	500	32
43	**1**	**49.2**			32.5
44	**0**	**48.5**	32	525	33
44	**2**	**47.8**			33.5
45	**1**	**47.1**	33	525	34
46	**0**	**46.4**			34.5
46	**2**	**45.7**	34	550	35
47	**1**	**45.1**			35.5
48	**0**	**44.4**	35	550	36

Tab. D.1: 4ST3, 4RE3, DEAD parameters and expected trigger latency for different drift velocities. ST values correspondent to 4ST3 and 4RE3 parameters. 2ST, 3ST, 4ST, 5ST and 7ST are equal to ST multiplied by 2, 3, 4, 5 and 7 respectively.

APPENDIX E: CHIP VALIDATION USING BIST CIRCUIT.

Chip validation is simplified if internal built-in self test circuitry is used. This block allows to exert all track patterns at high speed with a programmed track angle and position. The test sequence consists of the following steps:

E1: Initial configuration file setup and validation test start

The BTI Config register file is programmed for chip validation: all wire enable masks are set high (WEN=111111111), wire dead time is the maximum possible (DEAD=111111), all trigger angle windows are set to the limits (high=111111 low=000000) and any combination of ACx is accepted.

The BTI Test register file is programmed for validation: all pattern masks are set high (PTMSK=$FFFFFFFF), all equation counter group masks are disabled (TCEN=$000). As described in Appendix B equation counters are grouped into 12 ensembles with an individual counter enable bit in TCEN. Test sequence starts pulling low SYRSB, setting high RON, XON and TEST, equation counters are all enabled setting high the group mask (TCEN=$FFF). When SYRSB is released the test starts at the first rising clock edge.

E2: Equation counters settings

TCEN GROUP	Step	TCEN GROUP	Step
0	2	**6**	2/3
1	2	**7**	2/3
2	2	**8**	2/3
3	1	**9**	1
4	1	**10**	1
5	1	**11**	1

Tab. E.2.1: Equation counters step/cycle.

Group	15cy	+2cy	+14cy	+2cy	+14cy	+2cy	+13cy
0	1	0	0	0	0	0	0
1	1	1	0	0	0	0	0
2	1	0	0	0	0	0	0
3	1	1	1	0	0	0	0
4	1	1	1	1	0	0	0
5	1	1	1	0	0	0	0
6	1	1	1	1	1	0	0
7	1	1	1	1	1	1	0
8	1	1	1	1	1	0	0
9	1	1	1	0	0	0	0
10	1	1	1	1	0	0	0
11	1	1	1	1	1	1	1

Tab. E.2.2: TCEN sequence used to preset all equations to $1F.

All equations count starting from zero with a counting step to clock rate dependent on group:In order to scan all track patterns it is necessary to preset all equation counters to the same value. This is achieved during the counting sequence, disabling each group as soon as it has the right output value. For example to reach the common value $1F equation counter groups are enable for the number of cycles given in the following table:The group 0 and 2 are stopped (TCEN(0)=0) after 15 clock cycles, group 1 is stopped 2 cycles later, group 3, 5 and 9 are stopped 14 cycles later. At the 62th cycle when group 11 is stopped all equation counters have the same value ($1F in this case).

E3: Track patterns sequencing

When all equation counters are preset to the same value track patterns can be enabled one by one using the validation sequencer. The execution starts setting high the VALTST flag. Each pattern is tested for an equation coincidence in different conditions as given in the following table:

Each trigger pattern needs 13 clock cycles to try all the test conditions, this means that track patterns are all tested with 832 cycles. Of course to reach a good fault coverage the validation sequence must be repeated for at least two different equation counters values and with different drift velocity parameters. The validation sequence repeated for angle values $1F and $20 gives a net toggling coverage around 92%.

Seq. cycle	XON	RON	XA	XB	XC	XD	Conditions
1	1	1	1	0	0	0	Rid. on, Xeq on, Low -A
2	1	0	1	0	0	0	Rid. off, Xeq on, Low -A
3	0	0	1	0	0	0	Rid. off, Xeq off, Low -A
4	1	1	0	1	0	0	Rid. on, Xeq on, Low -B
5	1	0	0	1	0	0	Rid. off, Xeq on, Low -B
6	0	0	0	1	0	0	Rid. off, Xeq off, Low -B
7	1	1	0	0	1	0	Rid. on, Xeq on, Low -C
8	1	0	0	0	1	0	Rid. off, Xeq on, Low -C
9	0	0	0	0	1	0	Rid. off, Xeq off, Low -C
10	1	1	0	0	0	1	Rid. on, Xeq on, Low -D
11	1	0	0	0	0	1	Rid. off, Xeq on, Low -D
12	0	0	0	0	0	1	Rid. off, Xeq off, Low -D
13	1	1	1	1	1	1	Rid. on, Xeq on, High

Tab. E.3.1: Track pattern test sequence of conditions.
